

For me, as an amateur looking at commercial SAR data for the first time, identifying destroyed aircraft was very difficult. The main problem is that SAR images do not look like optical images, and the shape of the aircraft can change strongly depending on the viewing geometry, radar angle, shadows, and bright radar reflections.

The only reliable method I found was to compare aircraft of the same or similar type that were parked at a similar angle to the radar. Without this comparison, I do not think I could confidently verify whether a small aircraft was destroyed or simply looked different because of its orientation.

For larger aircraft, when the damage is significant, it is easier to recognize destruction because there are visible changes around the aircraft on the ground. The asphalt surface helps a lot, because it provides a relatively regular background, and damaged aircraft or debris create strong radar scattering. Bright irregular reflections, disturbed shapes, and changes around the parked aircraft were the main features I used to distinguish destroyed aircraft from intact ones.

However, if the aircraft had been located on an irregular surface, such as grass or natural terrain, I think it would have been much harder to identify even the large destroyed aircraft. The background would create more noise and make the debris pattern more difficult to separate from normal surface texture.

I was able to identify only two small aircraft with reasonable confidence. The third example is highly uncertain, because the aircraft appears to be parked at a different angle, which makes comparison difficult. For this reason, I marked it as a possible destroyed aircraft, but with a large question mark.
